!

I change everywhere!

Abstract

We analyze the fiscal competition between city governments in China by structurally estimating a Bertrand pricing game model. The model characterizes the land pricing strategy of city governments as they use land sales discounts to attract industrial firms. Our results imply that city governments can generate a huge amount of fiscal revenue from landing industrial firms, which is around 46% of the firm's yearly output. We show that the impact of this kind of fiscal competition on resource allocation is very limited by counterfactual experiments. Simulation results also show that fiscal centralization and increasing urban wages will raise the average land price.

Why couldn't this just be measured? Unobserved?

1 Introduction

In this paper, we analyze the fiscal competition between city governments in China as they use industrial land sales discounts to attract industrial firms to land in their geographical jurisdictions. ~~This topic is interesting since~~ the unique “regionally decentralized authoritarian regime” (Xu, 2011) plays an important role in China’s economic growth. This regime is unusual in combining a high degree of political centralization and economic decentralization, and it gives local officials great autonomy in economic and fiscal issues (Kroeber, 2020; Xiong, 2018). Thus, local officials have strong incentives to develop the local economy as well as maximize their fiscal revenues. One of the most salient characteristics of the system is the competition among city governments, which use special deals to attract businesses (Bai et al., 2020). ~~And a~~ major type of special deals is selling industrial lands at low prices to firms (Su and Tao, 2017). Thus, our study helps to understand the economic system of China, and it also sheds light on broader public economics issues, especially the mechanism and impacts of fiscal competition caused by the decentralization of economic and fiscal power.

Our analysis is based on a Bertrand pricing game model that characterizes the fiscal competition between Chinese city governments. In this model, city governments maximize their fiscal revenue by providing special industrial land price offers to attract firms, and they need to consider competitor city governments’ strategies when they make land price offers. The basic trade-off in the model is between the higher probability of getting the firm and higher land-selling revenue. We solve the continuous Bertrand pricing game using the Gauss-Seidel algorithm, and structurally estimate the key parameters of this model by the method of simulated moments (MSM), which is numerically implemented by a polyalgorithm combining the grid search and Quasi-Newton method.

The estimation results show city government can generate a huge amount of fiscal revenue from landing industrial firms, and the total fiscal revenue is around 46% of the firm’s per year output level, which is far beyond the official tax revenue. This finding shows the fiscal spillover effects of landing industrial firms for city governments are enormous, and that’s why local governments in China compete against each other so fiercely to attract industrial firms. We use counterfactual experiments to study the impacts of this fiscal competition, and the results suggest this fiscal competition has very limited if no impacts on the ~~improvement of~~ resources allocation, ~~if~~ ^{assuming} the total output level is fixed. ~~And~~ we also simulate the impacts of fiscal power re-centralization and rising wages on this kind of fiscal competition, and the results show that both fiscal power re-centralization and the rising urban wage will raise industrial land prices

Understanding this process is important because

try to avoid excessive use of γ and

moderately.

A large strand of literature studies the decentralization of economic and fiscal power in China, particularly, [Cheung \(2014\)](#), [Su and Tao \(2017\)](#), [Bai et al. \(2020\)](#) and [Liu and Xiong \(2020\)](#) all notice that local governments in China use land sales discounts to attract firms. [Chen et al. \(2017\)](#) constructs a land price index in China and finds that price of industrial land in China is significantly lower than commercial and residential land. [Bai et al. \(2020\)](#) also confirms the fact by regression analysis. But these papers don't build any formal economic model on this issue. For general theoretical discussion on the impacts of fiscal competition, literature built on [Tiebout \(1956\)](#) emphasizes the welfare improvement effect caused by competition for mobile capital~~s~~, which creates efficient equilibrium. However, literature on the tax competition model~~s~~ ([Keen and Marchand, 1997](#); [Wilson, 1999](#)) emphasizes the downward pressure on fiscal revenue induced by fiscal competition and the possibilities of "race to the bottom". See [Wilson \(1999\)](#) for a literature survey for this research area.

For the structural estimation, our work is closest to [Mast \(2020\)](#), which estimates a Bayesian game between towns in the U.S. as they use tax breaks to bid for firms. Two key differences are that we explicitly model the cost minimization problem of the firms, and we solve the game on a continuous space rather than on grids. And our numerical methods for solving the game and estimation are both fast.¹

The outline of the paper is as follows: In [Section 2](#) we examine the evolution of fiscal competition between local governments in China and its relation with the land market. [Section 3](#) presents our model and the numerical method to solve the model. [Section 4](#) and [Section 5](#) describe the data and our estimation method. [Section 6](#) shows the estimates and the fit of our model. [Section 7](#) shows the counterfactual analysis based on the estimates. And [Section 8](#) concludes.

2 Fiscal Competition and Land Market in China

As discussed in [Section 1](#), city governments in China use low land prices to attract industrial firms to produce in their jurisdictions. In this section, ~~we~~^{we} briefly review the evolution of this kind of fiscal competition and its impact on China's land market from a historical perspective, which will provide a basis for ~~our~~^{our} model introduced in [Section 3](#).

¹It costs around 15 minutes to get the main estimation results in [Section 6](#) on the author's PC with Core i7-1165G7 (2.80GHz) CPU and 16 GB RAM.

2.1 The evolution of fiscal competition between local governments

The reason why Chinese local governments compete fiercely against each other to attract industrial firms is deeply rooted in China's fiscal system, especially the fiscal revenue sharing scheme between the central government and local governments. China began its economic reform as a very poor country in 1978, and the central government uses "fiscal contracting" system in the 1980s to incentivize local governments to develop the local economy. Under this system, local governments get an increasing marginal share of the fiscal revenue they collected. Moreover, they often collude with local state-owned enterprises (SOEs), which generate most of the tax revenue in the 1980s, to hide the fiscal revenue from the central government (Su and Tao, 2017).

The "fiscal contracting" system led to a continuous decline of the central government's share of total fiscal revenue and threatened the stability of China's macro economy though it enriches the local governments (Liu and Xiong, 2020). The Tax-sharing Reform in 1994 changed this situation drastically by reconstructing the tax system. Under this new system, fiscal revenue sharing based on fiscal contracting is abolished, and the central government takes the larger part of tax revenue collected by local tax bureaus, which are controlled by the central government directly since then. The tax revenues left to local governments ^{comprises} are 25% of value-added tax (VAT), business tax, and income tax.² Meanwhile, local governments had to accept more obligations for public spending. To make matter worse, low-efficient local SOEs were hard to survive under the competition with private and foreign firms, which are thriving in China since the mid-1990s. As a result of these dramatic changes in China's fiscal system, local governments had to find new ways to generate more fiscal revenues to make up for their fiscal shortfall. ^{the} ~~And a~~ natural choice for local governments is to attract private (including foreign) firms to land in their jurisdictions. In addition to the trivial benefits of tax revenue generated by landing private firms, ^{the} ~~the~~ huge fiscal spillover effects include the promotion of local business since more workers come to the city, and the land sale revenue promoted by the increasing demand in the residential and commercial housing market, which will be discussed in the next subsection. The strong incentives for attracting firms lead to fiscal competition between local governments. Selling industrial land at low prices is the most common method of attracting firms between competing cities.

²The central government also takes 60% of income tax since 2003.

2.2 The land market in China

All land in China belongs to the state legally, however, local governments, especially city and county governments have de facto ownership over land in their jurisdictions.³ Thus, local governments are the de facto monopolist of land supply in their jurisdictions though the upper bound of land supply is dependent upon the land quota set by the central government.

For residential and commercial land, as the monopolist of ~~land~~, the local governments tend to rise the ~~land~~ price by restricting the supply of land of these two types. According to the national land price index constructed by Liu and Xiong (2020),⁴ the price ~~index~~ of commercial land in China rose from 1 in 2004 to 6.11 in 2015, and which of residential land rose from 1 to 4.75 during the same period.

But for industrial land, the story is different. According to Liu and Xiong (2020), the price index of industrial land in China was just 1.5 in 2015 (starting from 1 in 2004). Nevertheless, suppressing industrial land prices is also a rational strategic choice of local governments. By making special deals with firms, the local governments use low land prices to attract firms to ~~land in~~ their jurisdiction.⁵ And because a firm is always attracted by several cities, the firm will often get an upper hand in bargaining with city governments. Thus, the land price will become lower as the competition becomes fiercer.

Assuming ~~Notice~~ that workers ~~will~~ always live in the city where they work, they don't have too much freedom to choose where to buy houses.⁶ And since the service industry (local businesses) ~~always~~ thrives in cities that have many industrial firms and a large consumption market (which is brought by the large working population), commercial enterprises don't have too much freedom to choose their locations, either. Thus, local governments can extract consumer surplus in both the residential and commercial land markets, which ~~can~~ *may* not only compensate for their loss in industrial land sales but also bring huge additional profits since the demand for residential and commercial land increases sharply if more industrial firms produce in their jurisdictions.

Having ~~After~~ *ed* introducing the background of fiscal competition in China, ~~we will~~ *build a* model the fiscal competition in the next section. *of*

³The Land Management Law passed in 1998 authorizes local governments to sell usufruct rights over the land. See Liu and Xiong (2020).

⁴The land price index in Liu and Xiong (2020) is based on the data and calculation of Chen et al. (2017).

⁵The industrial lands are sold through case-by-case negotiations and open auctions in China. In the first case, the special deal is easily achieved. ~~And in~~ the second case, which is promoted by the central government to prevent corruption and fiscal revenue waste by selling lands at low prices, the special deals can be also realized by sending signals in the first stage of the auction to deter the entry of other bidders (Cai et al., 2013).

⁶Actually, only a part of workers like advanced engineers and managers buy houses in cities, most manufacturing workers coming from rural areas don't buy houses in cities due to their low wage level and institutional discrimination (the hukou system). And that's why the high residential housing price doesn't raise the wage cost of industrial firms and influence their location choices.

3 The Model

3.1 General settings

We use a Bertrand pricing game model to characterize the fiscal competition between Chinese city governments. In this model, each new firm⁷ signs a contract of producing a given amount of output at given prices with the buyers on the global market. ~~After knowing the output level,~~ ^{with fixed} each ~~new~~ firm makes a short list of potential cities for building its factories, then the firm solves the production cost minimization problem and builds its factories in the city that is in its choice set and has the lowest production cost.⁸

The production cost of each firm is composed of four parts in the model:

- (i) Capital cost: We assume that the price of capital is the same across the country.
- (ii) Labor cost: We assume that each city has a wage level determined by the local labor market. An individual firm is just a price-taker in the labor market.
- (iii) Land cost: The industrial land price is completely controlled by the city government, and the city government makes a special land price offer for each firm considering landing in its jurisdiction.
- (iv) Other costs: all other costs (dependent on both firm and city characteristics) are included in the error term of the model, the distribution of which is common knowledge for all city governments.

The city governments maximize their expected fiscal revenue by attracting firms to land in their jurisdictions. We should notice that the term “fiscal revenue” here is most broadly defined, which includes but is not limited to tax revenue, promotion of local business and housing market, political benefits, etc., i.e. all the potential benefits generated by landing firms.

The channel by which city governments attract firms is to provide special industrial land price offers to the firms. Since the output level of each firm is common knowledge for all city governments in the firm’s choice set, the city governments can adjust the production cost of a firm by changing the land price offered to the firm. This will change the probability of the firm to land in this city as well as the expected fiscal revenue for the city government to attract the firm. And to determine the land price, a city government must consider the land prices offered by other city governments, since the other city governments’ price choices will also impact the

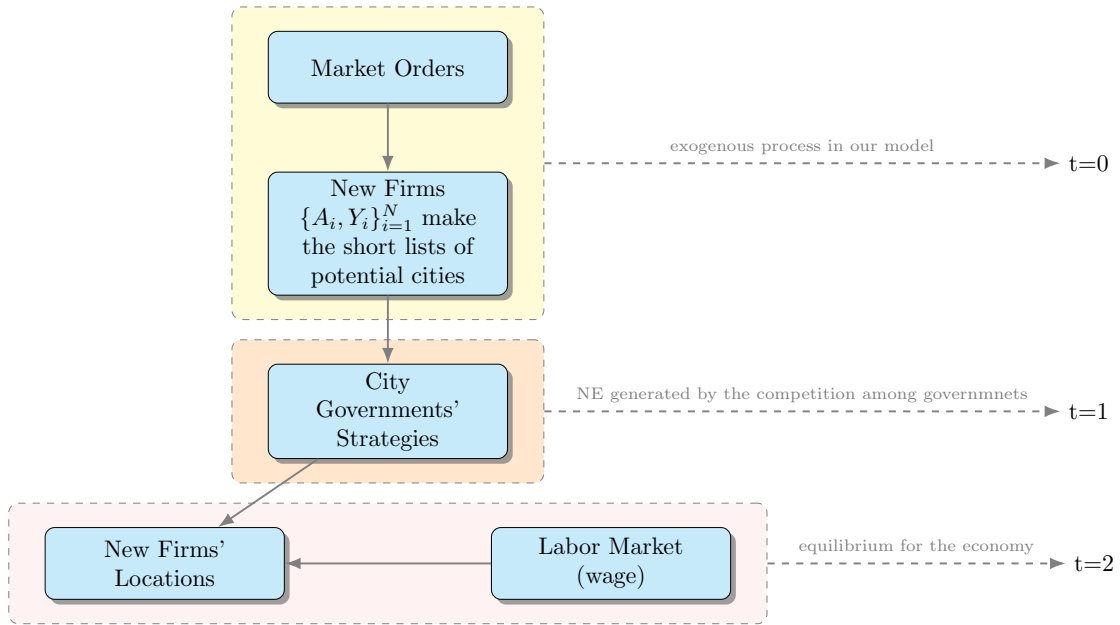

⁷The “firms” defined in this paper are private firms (Chinese private firms and foreign firms). State-owned firms are excluded from analysis since the goal of state-owned firms cannot be simply characterized as profit maximization, and they don’t have absolute freedom to choose their locations.

⁸We think the assumption is valid since an individual firm has only limited information and political resources, so it can only deal with a limited number of city governments.

probability of the city getting the firm as well as the city's expected fiscal revenue. Thus, we use a Bertrand pricing game model to characterize the interaction of city governments when they make the land offers. At the Nash equilibrium of this game, each city government has no incentive to change its land offer since the land price at the equilibrium has already maximized its expected fiscal revenue given other cities' land offers in the equilibrium strategy profile.

The main structure of the model implied in the discussion above can be described using Figure 1 below:

Figure 1: Main structure of the model

Notes: The figure presents the main structure and timing assumptions of the model. Solid arrows represent causal channels in the model. We use the productivity of firm i , A_i and the output level Y_i to characterize firm i in this figure.

Next, we describe the cost minimization and location choice problems faced by firms, then we write down the expected fiscal revenue maximization problem faced by city governments as well as the Bertrand pricing game between city governments. Finally, we define the Nash equilibrium (NE) in this game and prove the uniqueness of NE.

3.2 Firms

We ~~denote~~ ^{index} new private firms by $i = 1, 2, 3, \dots, N$; cities and city governments by $k = 1, 2, 3, \dots, M$. Each firm i is characterized by its output level Y_i as well as its pro-

duction function F_i , which is a mixture of Cobb-Douglas and Leontief technology:

$$F_i(K, L, T) = \min \{A_i K^\alpha L^{1-\alpha}, g_i(T)\}.$$

where A_i is the productivity of firm i , K is the amount of capital firm i uses in production, L is the number of workers in firm i , T is the area of industrial land firm i uses, and $g_i(\cdot)$ is a strictly increasing function. Notice that in this production function, capital and labor can substitute each other, and the land is the pure complement for capital and labor. This setting reflects the fact that land is a special input, which restricts the maximum output level of capital and labor. It also reflects the no-waste assumption, i.e., firms make full use of the lands.

Given the output level Y_i firm i needs to produce, it chooses a city k in its choice set \mathbf{C}_i (the short list of candidate cities) to build the factory, as well as the amount of capital input K_i per year, number of workers L_i and the area of industrial land T_i . Thus, firm i solves the following cost minimization problem:

$$\begin{aligned} \min_{k \in \mathbf{C}_i, K_i, L_i, T_i} & \left\{ rK_i + w_k L_i + \frac{p_{ik}}{m} T_i - \varepsilon_{ik} \right\} \\ \text{s.t. } & Y_i = \min \{A_i K_i^\alpha L_i^{1-\alpha}, g_i(T_i)\}, \end{aligned}$$

where r is the price of capital, which is assumed to be a constant in the whole country; w_k is the wage level in city k , which reflects firm i is just a price taker in the labor market; p_{ik} is the industrial land price city government k offers to firm i ; m is the term of land lease.⁹ We divide p_{ik} by m so that the time scales for all variables are unified to a year, and the firm is minimizing the production cost per year. And ε_{ik} in the production cost is an error term, which is assumed to have type I extreme value distribution with scale parameter σ . It represents all other unobserved costs and benefits for the firm i to produce in city k .

Furthermore, we normalize the price of one unit of product to be 1 yuan (RMB) in the global market. Finally, we assume the size of the candidate set $|\mathbf{C}_i| = l(Y_i)$ and $l(Y_i)$ is a nondecreasing function in Y_i since larger firms have more information and political resources so that they can deal with more local governments.

From the structure of the constrained minimization problem faced by firm i , we know that firm i always chooses T_i s.t. $Y_i = g_i(T)$. And the firm's cost minimization problem changed to:

$$\begin{aligned} \min_{k \in \mathbf{C}_i, K_i, L_i} & \left\{ rK_i + w_k L_i + \frac{p_{ik}}{m} g_i^{-1}(Y_i) - \varepsilon_{ik} \right\} \\ \text{s.t. } & Y_i = A_i K_i^\alpha L_i^{1-\alpha} \end{aligned}$$

⁹We drop the subscript of m since the terms of the land lease in our data set are all 50 years.

Reformulate as
"characterise firms' minimising
choice" or smth like that

We use a two-step method to solve (2), first we solve the cost minimization problem for each city $k \in \mathbf{C}_i$; then we find the city which has the lowest production cost for firm i :

- (i) If firm i chooses to land in city k , then it should choose K_i and L_i to minimize its production cost. F.O.Cs of this problem show:

$$L_i = \left(\frac{1-\alpha}{\alpha}\right)^\alpha \left(\frac{r}{w_k}\right)^\alpha \frac{Y_i}{A_i} = B_i w_k^{-\alpha} \quad (3)$$

and

$$K_i = \frac{\alpha}{1-\alpha} \cdot \frac{w_k}{r} \cdot L_i = \frac{\alpha}{r(1-\alpha)} B_i w_k^{1-\alpha} \quad (4)$$

where $B_i := \left(\frac{(1-\alpha)r}{\alpha}\right)^\alpha \frac{Y_i}{A_i} = L_i w_k^\alpha$ only depends on the firm i 's characteristics.

- (ii) With a little abuse of notations, we denote the optimal level of land area for firm i by T_i in all the remaining parts of this paper, i.e. $T_i := g_i^{-1}(Y_i)$. Plug (3) and (4) into the cost function in (1), and we know the total cost c_{ik} of producing in city k for firm i :

$$\begin{aligned} c_{ik} &= w_k \cdot L_i + r \cdot K_i + \frac{p_{ik}}{m} \cdot T_i - \varepsilon_{ik} \\ &= \frac{1}{1-\alpha} B_i w_k^{1-\alpha} + \frac{p_{ik}}{m} T_i - \varepsilon_{ik} \end{aligned} \quad (5)$$

Now the firm just needs to choose the best location $k^* = \operatorname{argmin}_{k \in \mathbf{C}_i} c_{ik}$. Notice in the model, the exact value of ε_{ik} is the private information of firm i , but the type I extreme value distribution of ε_{ik} with scale parameter σ is common knowledge among all city governments.

Thus, city governments in firm i 's choice set \mathbf{C}_i can calculate the probability of firm i landing in their jurisdictions though they don't know the actual location choice of the firm in advance. We denote $P_{ik}(p_{ik}, p_{i(-k)}) := \Pr(i \text{ lands in } k | p_{ik}, p_{i(-k)})$, and we have:

Remove Eq. everywhere,
only (v) is needed

$$\begin{aligned} P_{ik}(p_{ik}, p_{i(-k)}) &= \Pr(c_{ik} < c_{ij} \ \forall j \in \mathbf{C}_i \setminus \{k\}) \\ &= \frac{\exp\left[\left(-\frac{1}{1-\alpha} B_i w_k^{1-\alpha} - \frac{p_{ik}}{m} T_i\right)/\sigma\right]}{\sum_{j \in \mathbf{C}_i} \exp\left[\left(-\frac{1}{1-\alpha} B_i w_j^{1-\alpha} - \frac{p_{ij}}{m} T_i\right)/\sigma\right]} \end{aligned} \quad (6)$$

where Eq (6) is the logit formula derived by McFadden (1974), and $p_{i(-k)}$ is the vector of land prices offered by all cities in $\mathbf{C}_i \setminus \{k\}$.

3.3 City governments

Now we can turn to the government's expected revenue maximization problem. We assume the city government's revenue ~~gotten~~ from attracting new firms to land in its jurisdiction is

composed of two parts: (i) the fiscal revenue generated by the new firm itself, which includes tax revenue, promotion of local business and housing market, political benefits, etc, as discussed in Section 2, and (ii) the fiscal revenue generated by selling the industrial land. More specifically, we set:

$$v_{ik} = P_{ik}(p_{ik}, p_{i(-k)}) \cdot (\beta Y_i + p_{ik} T_i) = \frac{\exp\left[\left(-\frac{1}{1-\alpha} B_i w_k^{1-\alpha} - \frac{p_{ik}}{m} T_i\right) / \sigma\right]}{\sum_{j \in \mathbf{C}_i} \exp\left[\left(-\frac{1}{1-\alpha} B_i w_j^{1-\alpha} - \frac{p_{ij}}{m} T_i\right) / \sigma\right]} \cdot (\beta Y_i + p_{ik} T_i) \quad (7)$$

where v_{ik} is the expected fiscal revenue for city government k to attract firm i ; the first term in the RHS of (7) is the probability of firm i to land in city k which we get in (6); the second term in the RHS of (7) is the city government's revenue ~~got~~ from attracting new firms to land in its jurisdiction. More specifically, βY_i is the fiscal revenue generated by the new firm itself, where $\beta \geq 0$ can be interpreted as the revenue share of city governments in the output of the firm,¹⁰ and $p_{ik} T_i$ is the ~~land~~ selling revenue from selling the land.

Equation (7) shows the basic trade-off between the higher land-selling revenue and the higher probability of getting the firm. The higher land price can bring a city government higher land-selling revenue if it can get the firm, but the higher land price will also lower the probability of the firm choosing this city.

Notice that v_{ik} is not only dependent on city k 's land price offer p_{ik} , but also dependent on other competitor cities' land price offers $p_{i(-k)}$, which implies nothing but each city government should consider other city governments' land pricing strategy when it tries to solve its own expected fiscal revenue maximization problem. And this observation leads us to model the interaction between city governments in the game-theoretic framework.

3.4 Bertrand pricing game

As mentioned at the end of Section 3.3, we model the interaction between city governments by a Bertrand pricing game model. More explicitly, for each new firm i , the cities in its choice set \mathbf{C}_i play a pricing ~~Bertrand~~ game to determine the probabilities of firm i choosing each of these cities, i.e. each city in \mathbf{C}_i picks a probability distribution of land price on the common action space as its strategy to maximize its expected fiscal revenue. At the Nash Equilibrium (NE) of the game, each city has no incentive to change its strategy given other cities' strategies. Now we formally define the game and the NE:

¹⁰Since the "fiscal revenue" here is most broadly defined as all the revenue the firm brings to the city government directly and indirectly in the whole term of the current officials, $\beta > 1$ is possible. And we assume the fiscal revenue is positively proportional to the scale of the firm measured by its output level per year.

this is mixed strategy ¹⁰ ruled out on the next page

The Bertrand game for attracting firm i is denoted by $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$, where \mathbf{C}_i is the set of players, i.e. the city governments in firm i 's choice set; S_{ik} is the action space for each player, and we stipulate that $S_{ik} \equiv S_i = [p_{min}^i, p_{max}^i]$ for $\forall k$; ¹¹ and the payoff function v_{ik} is just the expected fiscal revenue function we defined in (7). We can define pure strategy Nash equilibrium of the Bertrand game as below: ¹²

Definition 1 (Nash Equilibrium). For all i , a strategy profile (price vector) $p_i^* \in S_i^{|\mathbf{C}_i|}$ is pure strategy Nash Equilibrium (NE) if for all $k \in \mathbf{C}_i$ and $p_{ik} \in S_i$,

$$v_{ik}(p_{ik}, p_{i(-k)}^*) \leq v_{ik}(p_{ik}^*, p_{i(-k)}^*).$$

Now we consider the properties of NEs in the Bertrand Game. First, we analyze the best response function in this game. Next, we prove the existence and uniqueness of pure NE.

Without loss of generality, we consider a city government k in \mathbf{C}_i trying to attract firm i , and analyses the city government k 's best response given other competitor cities' land prices.

First we derive the partial derivative of v_{ik} w.r.t. p_{ik} :

$$\frac{\partial v_{ik}}{\partial p_{ik}} = T_i P_{ik}(p_{ik}, p_{i(-k)}) \cdot \left[1 - \frac{1}{\sigma m} (1 - P_{ik}(p_{ik}, p_{i(-k)})) (\beta Y_i + p_{ik} T_i) \right] \quad (8)$$

Notice that the first term in (8): $T_i P_{ik}(p_{ik}, p_{i(-k)}) > 0$, we fix $p_{i(-k)}$ and define:

$$f(p_{ik}) := 1 - \frac{1}{\sigma m} (1 - P_{ik}(p_{ik}, p_{i(-k)})) (\beta Y_i + p_{ik} T_i)$$

The derivative of $f(p_{ik})$ is:

$$f'(p_{ik}) = -\frac{1}{\sigma m} \cdot \left[\underbrace{-\frac{\partial P_{ik}(p_{ik}, p_{i(-k)})}{\partial p_{ik}}}_{<0} \underbrace{(\beta Y_i + p_{ik} T_i)}_{>0} + \underbrace{(1 - P_{ik}(p_{ik}, p_{i(-k)}))}_{>0} T_i \right] \quad (9)$$

And it can be shown:

$$\begin{aligned} \lim_{p_{ik} \rightarrow -\infty} f(p_{ik}) &= 1 \\ \lim_{p_{ik} \rightarrow +\infty} f(p_{ik}) &= -\infty \end{aligned} \quad (10)$$

Combining (8), (9) and (10), ~~we know~~ ^{it is clear} that for any $p_{i(-k)}$, $\exists \zeta \in \mathcal{R}$ s.t. $\frac{\partial v_{ik}}{\partial p_{ik}} > 0$ for all $p_{ik} < \zeta$, $\frac{\partial v_{ik}}{\partial p_{ik}} > 0$ for all $p_{ik} > \zeta$, and $\frac{\partial v_{ik}}{\partial p_{ik}} \Big|_{p_{ik}=\zeta} = 0$. Based on this observation, we have the following theorem:

¹¹We use p_{min}^i to reflect the participation constraint of city governments in \mathbf{C}_i (governments can't set the land price smaller than the cost of land), p_{max}^i to reflect the participation constraint of firm i (firms will not build factories if the land price is extremely high).

¹²We don't consider mixed strategy Nash equilibrium in this paper.

Mismatch in assuming closed intervals and looking at limits

See prev page

development

Name does not match the statement of the theorem

Theorem 1 (Uniqueness of Best Response). For any Bertrand Game $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$ and any city government k in \mathbf{C}_i , given other city governments' land price profile $p_{i(-k)}$, k 's best response p_{ik}^* ~~satisfies~~ is uniquely given by \leftarrow

$$p_{ik}^* = \begin{cases} p_{min}^i, & \text{if } f(p_{min}^i) \leq 0 \\ p_{max}^i, & \text{if } f(p_{max}^i) \geq 0 \\ \text{the root of } f(p_{ik}) = 0, & \text{if } f(p_{min}^i) > 0 \text{ and } f(p_{max}^i) < 0 \end{cases} \quad (11)$$

Uniqueness in the statement

This should be done from the start

The proof of Theorem 1 is in Appendix A.

$G: \dots \rightarrow \dots$

to skip

To prove the existence and uniqueness of pure NE, we first define a mapping G . For any Bertrand Game $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$, we set $N = |\mathbf{C}_i|$ and define $G: S^N \rightarrow S^N$ s.t. $G(p) = p'$:¹³ for $k = 1$, p'_k is the best response of city k given other cities' land price profile (p_2, \dots, p_N) ; for $2 \leq k \leq N$, p'_k is the best response of city k given other cities' land price profile $(p'_1, \dots, p'_{k-1}, p_{k+1}, \dots, p_N)$; for $k = N$, p'_k is the best response of city k given other cities' land price profile (p'_1, \dots, p'_{N-1}) . And we have the following theorem:

Not sure case $k=1$ needs to be special

(C;| notation earlier.

Also,

No?

Theorem 2 (Uniqueness of Pure NE). Every Bertrand Game $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$ has a unique pure strategy Nash Equilibrium p^* . Moreover $G^n(p) \rightarrow p^*$ for any $p \in S_i^N$ as $n \rightarrow \infty$.

is this defined?

Is this defined? (with superscript)

The proof of Theorem 2 is in Appendix A.

3.5 Numerical method of solving the model

Now we consider the numerical method used to solve the Bertrand Game.

Theorem 1 and Theorem 2 immediately provide us a numerical solver of the game based on the Gauss-Seidel algorithm (see Algorithm 1): we can start from an initial strategy profile (price vector), and for each city, we calculate the city government's best response given others' land prices, then update the city's strategy. And we repeat this process until the price vector converges, i.e. NE is found. The algorithm is described below:

Notice that the inner loop of Algorithm 1 is the mapping G defined in Section 3.4. Thus, the outer loop always stops and successfully returns the price vector according to Theorem 2. And the output price vector is sufficiently close to the pure NE price vector p^* given the small enough tolerance level.

¹³The subscript i is dropped here for brevity.

"Computing fixed point of contracting mapping G using successive approximation algorithm implemented with Gauss-Seidel iterations"

Algorithm 1: Gauss-Seidel algorithm to solve the Bertrand Game $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$

Input: any initial price vector p_i ;
 action space $[p_{min}^i, p_{max}^i]$;
 $tol \leftarrow 1e-3$;

/* Convergence criteria */

Result: a price vector sufficiently close to NE p^*

repeat

$p_i^0 = p_i$
 for k in $1 : |\mathbf{C}_i|$ do
 if $f(p_{ik} = p_{min}^i) \leq 0$ then
 $p_{ik} \leftarrow p_{min}^i$
 end
 else if $f(p_{ik} = p_{max}^i) \geq 0$ then
 $p_{ik} \leftarrow p_{max}^i$
 end
 else
 $p_{ik} \leftarrow$ the root of $f(p_{ik}) = 0$
 end
 end

until $\max_k (abs(p_{ik}^0 - p_{ik})) < tol$;
 return p_i

This should be 10^{-12}

As before N_i

It would be nice to add a para on the speed of convergence of the algo, what is the Lipschitz constant is.
 (modulus of contraction)

4 Data

In this section, we briefly introduce the data we use for estimation. We use the firm-land-city data in the year 2012 since our model is a static one, and the number of observations in 2012 is the largest. Another reason we choose 2012 data is that after 2013, the autonomy of local governments decreases due to the change in the political environment. Thus, data after 2013 may not be fully suitable for our model.

4.1 Data sources

First, we use the 2013 Chinese industrial firm survey to get the output level,¹⁴ the number of workers, the area of industrial land usage of the industrial firms newly established in 2012, and we also know the cities where these new firms choose to locate in. We should also notice that the firms recorded in the Chinese industrial firm survey are “enterprises above designated size”, which means the firms with output levels greater than or equal to five million yuan per year. Thus, our estimation is restricted to these large industrial firms in China, which are the focus of our model.

Second, we use the land selling data from *www.landchina.com* to get the industrial land

¹⁴We use the operation revenue of a firm as its output level since we normalize the price of the product to 1 yuan in our model. And we delete some problematic observations in the survey data, i.e. firms with zero operation revenue and firms with less than ten workers.

selling data in 2012. The website is operated by the Ministry of Natural Resources of China, which is a reliable data source. And the land-selling data including the areas, prices, and firms which buy the land.¹⁵

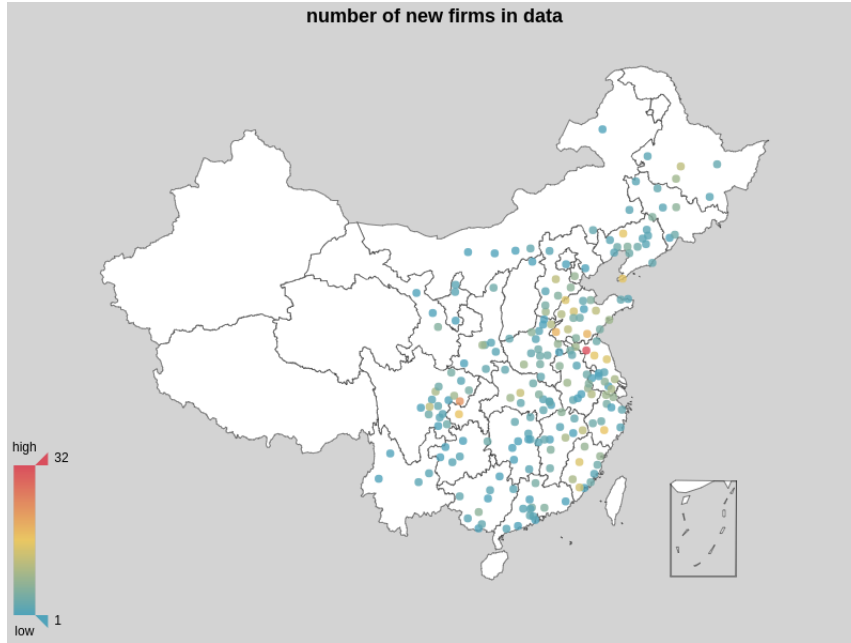

Third, we use the China city statistical yearbook to get the average wage of each city.

Finally, we match these data and get the final data set, which includes 1019 observations. An observation is a firm's output level, labor usage, area of industrial land bought by the firm, the city where the firm chooses, and the average wage in this city.

4.2 Data descriptions

We visualize the spatial distribution of the observations in our data set in the following [Figure 2](#).

Figure 2: Number of firms each city lands in data

Notes: Each point in the map represents a city which lands at least one firm in our data set, and there are 213 such cities in our data set. The color of the point denotes the number of firms a city lands, and the number increases as the color changes from blue to red.

We draw the map of China in [Figure 2](#). Each point in the map represents a city that at least one firm chooses. The color of the point represents the number of firms which the corresponding city lands. There are 212 such cities (points in the map) in our data set, and we know there are 4 direct-administered municipalities (Beijing, Shanghai, Tianjin, Chongqing) and 293 prefecture-

¹⁵We delete the outliers in the land selling data, i.e. the lands with top 1% land price and bottom 1% land price (22 observations are deleted).

level cities in China, thus our data set covers roughly $\frac{2}{3}$ Chinese major cities,¹⁶ though several cities have far more observations than others.

We also show the descriptive statistics of the variables used for estimation in the following Table 1:

Table 1: Descriptive statistics of variables in model

	land price (1,000 yuan/hectare)	output (1,000 yuan/year)	number of workers (person)	area of land (hectare)	city wage (1,000 yuan/year)
mean	1685.10	170733.30	228.16	4.59	36.96
std	934.95	409499.05	143.57	5.65	18.69
min	379.50	5662.00	10.00	0.03	17.21
25%	978.62	38354.00	125.00	1.60	30.49
50%	1440.01	72909.00	223.00	2.83	34.73
75%	2015.52	164553.00	324.50	5.40	39.83
max	6001.56	7282607.00	2326.00	65.48	320.63
N	1019	1019	1019	1019	288

Notes: There are 1019 observations (new firms established in 2012) in our data set. The last column is the city average wage for 288 cities, which is very close to the total number of prefecture-level cities and direct-administered municipalities (297 cities) in China. And 25%, 50%, 74% in the table mean 25% percentile, median, 75% percentile respectively.

And particularly, Figure 3 shows the distribution of land price and firms' output level, which are the two most important variables in our model. From Figure 3 we notice that both the distributions of the output level of firms and the industrial land price are left-skewed, moreover, more than 80% of firms have output levels between 5 million and 250 million yuan per year, and most of the firms buy land with a price below 3 million yuan per hectare. This implies most of the industrial land is sold at relatively low prices in our data set, which is consistent with our observations in Section 1 and Section 2.

¹⁶There is no observation in several regions of China like Xinjiang, Tibet, Qinghai, and Hainan. However, there are few large industrial firms in these regions due to their geographic characteristics, thus, our data set still covers enough cities.

Figure 3: Sample distribution of output level and land price

Notes: The blue line in the graphs are kernel density plots. To make the first histogram clearer, we just draw the distribution of firms with output levels smaller than 2 billion yuan/year. There are several firms with output levels of more than 2 billion yuan/year, which makes the actual tail of the distribution of output fatter.

5 Estimation Method

5.1 Settings for calibration and estimation

We calibrate α in the model, then use the method of simulated moments (MSM) (Pakes and Pollard, 1989; McFadden, 1989; Gouriéroux and Monfort, 1996) to estimate β and σ in the model. The two reasons we choose to calibrate α is that first, α is difficult to estimate due to the potential identification problem, i.e., different combinations of (α, β, σ) may lead to the same distribution of NE land price.¹⁷ Second, since the key parameter in the model is β , we are satisfied with the estimation if the estimates $\hat{\beta}, \hat{\sigma}$ are robust under different calibrated α values.

More specifically, we choose the capital income share $\alpha = 0.5$ according to Zhu (2012) and Brandt et al. (2008). Besides setting $\alpha = 0.5$, we also do estimation for $\alpha = 0.33$ and 0.67 , which can show the robustness of the estimation.

We set the parameters space as $\beta \in [0, 2]$ and $\sigma \in (0, 1000]$ so that we can do the initial grid

¹⁷We tried to estimate α , and its standard error is greater than 1, which makes the estimate meaningless.

search for parameters. The parameters space is large enough since two times of yearly output of firms is ~~extremely~~ huge as the city governments' revenue share, and σ should not be too large to make the location choice irrelevant to city governments' land-selling strategies.

We also specify the action space of cities for the game of attracting firm i as $[p_{min}^i, p_{max}^i]$, where $p_{min}^i = \max\{0, p_{obs}^i - 2000\}$, $p_{max}^i = \max\{p_{obs}^i, p_{obs}^i + 2000\}$, p_{obs}^i is the observed land price offered to firm i in data. We use p_{min}^i to roughly characterize the participation constraints of cities since the cities will not sell the land to the firm if the cost of land cannot be covered by the land-selling revenue and fiscal revenue. And p_{max}^i is used to characterize the participation constraint of the firm since if the land price (a part of production cost) is too high, the firm will suffer loss. The action space we choose is neither too large nor too small (2000 is roughly one-third of the range of observed land prices). See [Appendix B.2](#) for robustness checks of other settings of the action space.

To estimate β and σ , we need to solve the games under different values of parameters. Thus, we first list all the parameters and variables (inputs) needed for solving the Bertrand Game $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$ as in the following [Table 2](#):

Table 2: Inputs in the Bertrand Game model

	Name	Interpretation	Source	Value/Range/Formula
Parameters	β	governments' revenue share	estimation	$[0, 2]$
	σ	scale parameter in the distribution of ε_{ik}	estimation	$(0, 1000]$
	α	capital income share	calibration	$\{0.33, 0.5, 0.67\}$
Variables	Y_i	output level of firm	data	
	L_i	number of workers in the firm	data	
	T_i	area of land usage	data	
	w_k	city average wage	data	
	B_i	firm's characteristic	data	$L_i w_{k^*}^\alpha$
	\mathbf{C}_i	firm's choice set	random draws	
	p_{obs}^i	observed land price for the firm	data	
	p_{min}^i	the minimum of possible land price	data	$\max\{0, p_{obs}^i - 2000\}$
	p_{max}^i	the maximum of possible land price	data	$p_{obs}^i + 2000$

Notes: In this table, w_k is the abbreviation of $\{w_k\}_{k \in \mathbf{C}_i}$. k^* is the city the firm actually lands (and we observe) in data. The specification of \mathbf{C}_i is written in the paragraphs below. $[p_{min}^i, p_{max}^i]$ is the action space for the cities in the game of attracting firm i .

If we have all the inputs defined in [Table 2](#), we could solve the equilibrium price vector p_i by using [Algorithm 1](#) for all observations (all firm i) in data. However, before we start to do the estimation, we need to specify \mathbf{C}_i (the choice set of the firm) in [Table 2](#) explicitly to obtain the parametric model.

~~We treat \mathbf{C}_i as a random shock of the model, and more specifically, we draw $|\mathbf{C}_i|$ cities~~

I ~~do not~~ simulate \mathbf{C}_i by repeatedly drawing. -

randomly from ten cities that are nearest to the city where the firm lands in data (the observed chosen city).¹⁸

To fully specify the generating process of the choice set, now we only need to know how the size of the set $|\mathbf{C}_i|$ is determined. In [Section 3](#) we set $|\mathbf{C}_i| = l(Y_i)$, and we define $l(Y_i)$ explicitly here:

$$l(Y_i) = \begin{cases} 3 & \text{if } Y_i \leq 33rd \text{ percentile of } Y \\ 4 & \text{if } 33rd \text{ percentile of } Y < Y_i \leq 67th \text{ percentile of } Y \\ 5 & \text{if } Y_i > 67th \text{ percentile of } Y \end{cases} \quad (12)$$

In another word, there are 33% firms that have 3, 4, and 5 candidate cities respectively. And what we assume here is the number of candidate cities of a firm is increasing in the scale (output level) of a firm. This is consistent with the intuition that large firms always have more political resources and are more valuable in the eyes of city governments, and are often attracted by more city governments. We use five as an upper bound for the number of candidate cities based on the intuition that the political resources of a firm to deal with city governments are limited. For robustness checks, we also do estimation under the two settings that (i) one-half of the firms have 3 candidate cities, the other half of the firms have 4 candidate cities. (ii) one-half of the firms have 4 candidate cities, and the other half of the firms have 5 candidate cities respectively, and the results are reported in [Appendix B.1](#).

5.2 Moment conditions

Now we construct the MSM estimator for the parameter β and σ . We define all the information of firm i as $Q_i \equiv \{Y_i, T_i, B_i\}$, and we denote all the parameters by $\theta = (\alpha, \beta, \sigma)$. And θ_0 are the true parameters. From the discussion in [Section 3](#) we know that if the distribution of the choice set \mathbf{C}_i is given, the distribution of land price at NE for firm i will also be determined, thus the expectation of the land price will be determined. We define $x_i \equiv [p_i, p_i^2]'$,¹⁹ and denote the conditional first and second order of land price by $h(x_i; \theta_0) \equiv E(x_i | Q_i; \theta_0)$. By the definition of conditional land price, we have:

$$E[x_i - h(Q_i; \theta_0) | Q_i] = 0 \quad (13)$$

Since the structural residual $x_i - h(Q_i; \theta_0)$ is orthogonal to any function of Q_i , we choose

¹⁸By “nearest” we mean the ten cities which have the shortest straight-line distances (between city centers) to the chosen city. The chosen city is included in the ten cities.

¹⁹ p_i is scaled by 10,000 since $p_{max} = 6001.56$ in data.

the instrument variables vector $Z_i = [1, Y_i, T_i, Y_i \times T_i]'$ for its simplicity.²⁰ And the moment conditions are:

$$E[Z_i \otimes (x_i - h(Q_i; \theta_0))] = 0 \quad (14)$$

where the expectation of Kronecker product is zero vector, i.e., each IV is orthogonal to the two-by-one structure residuals vector.

Since calculating the theoretical moment $h(Q_i; \theta)$ is computationally expensive,²¹ we use the simulated moment $\frac{1}{S} \sum_{s=1}^S \tilde{h}(Q_i, \mathbf{C}_i^s; \theta)$ to replace $h(Q_i; \theta_0)$, where $\tilde{h}(Q_i, \mathbf{C}_i^s; \theta) \equiv E(x_i | \mathbf{C}_i^s, Q_i; \theta)$, the number of simulations $S = 10$, and \mathbf{C}_i^s is randomly drawn as described in Section 5.1. The MSM estimator is defined by:

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \left(\sum_{i=1}^N Z_i \otimes \left(x_i - \frac{1}{S} \sum_{s=1}^S \tilde{h}(Q_i, \mathbf{C}_i^s; \theta) \right) \right)' W \left(\sum_{i=1}^N Z_i \otimes \left(x_i - \frac{1}{S} \sum_{s=1}^S \tilde{h}(Q_i, \mathbf{C}_i^s; \theta) \right) \right) \quad (15)$$

$$s.t. \quad \theta = (\alpha_0, \beta, \sigma), \quad 0 \leq \beta \leq 10, \quad 0 < \sigma \leq 1000$$

where α_0 is the calibrated α and W is the weighting matrix.

5.3 Numerical algorithm for estimation

In this section we discuss the numerical algorithm used to calibrate estimate β and σ . Showing that a global minimum of the MSM objective is found in nonlinear models is generally very difficult or impossible (Iskhakov and Keane, 2021), but we try to reach the global minimum as close as possible by combining the grid search and Quasi-Newton algorithm.

We do a two-stage MSM estimation. As mentioned in the last section, we calibrate α to 0.33, 0.5, and 0.67 respectively. For each α , in the first stage of estimation, we set the weighting matrix to the identity matrix I . Next we calculate the MSM objective for all the (β, σ) pairs on the grids $\{0, 0.1, \dots, 2.0\} \times \{100, 200, \dots, 1000\}$ and find the $(\tilde{\beta}, \tilde{\sigma})$ with the smallest MSM objective, which should be near the global minimizer. Then we use Quasi-Newton (L-BFGS) algorithm to do a finer search of the two parameters starting from $(\tilde{\beta}, \tilde{\sigma})$ to get the first stage estimates $(\hat{\beta}_0, \hat{\sigma}_0)$.

To do the second-stage estimation, we update the weighting matrix W as the sample analog of $\{\operatorname{Var}[Z_i \otimes (x_i - h(Q_i; \hat{\theta}_0))] + \frac{1}{S} \operatorname{Var}[Z_i \otimes (\tilde{h}(Q_i, \mathbf{C}_i^s; \hat{\theta}_0) - h(Q_i; \hat{\theta}_0))]\}^{-1}$, where $\hat{\theta}_0 = (\alpha_0, \hat{\beta}_0, \hat{\sigma}_0)$, and we use the average of 30 simulations to approximate the theoretical moments $h(Q_i; \hat{\theta}_0)$ for each observation i . We use Quasi-Newton (L-BFGS) algorithm to search the second-stage

²⁰ Y_i and T_i are also scaled to the interval $[0, 1]$.

²¹For example, if each firm only has three candidate cities, then to calculate the conditional moments for one firm at any given parameters θ , we need to solve $\binom{10}{3} = 120$ games.

estimates $(\hat{\beta}, \hat{\sigma})$, which minimizes the new criteria function with the updated W , starting from the first stage estimates $(\hat{\beta}_0, \hat{\sigma}_0)$.

We treat W as the optimal weighting matrix, and the estimated asymptotic covariance matrix of the second-stage estimates are $\frac{1}{N}(\hat{D}'W\hat{D})^{-1}$, where \hat{D} is the sample analog of the gradient D of moment conditions evaluated at $(\hat{\beta}, \hat{\sigma})$.

For the whole estimation procedure, we parallelize the calculation of the MSM objective by splitting the tasks of solving all the games into several chunks. And we let each CPU ^{to} solve ~~a~~ chunk of the games simultaneously to save the time of estimation.

6 Estimation Results

6.1 Structural estimates

We show the estimation results below:

Table 3: Estimates of Parameters ($3 \leq |\mathbf{C}_i| \leq 5$)

Calibrated α	Parameters	Estimates	Standard Error
0.33	β	0.506	0.041
	σ	174.933	24.227
0.5	β	0.460	0.034
	σ	176.569	25.002
0.67	β	0.470	0.035
	σ	182.283	25.001

As [Table 3](#) shows, the estimates of governments' revenue share β and the scale parameter of the error term σ are stable. $\hat{\beta}$ varies from 0.46 to 0.5, $\hat{\sigma}$ varies from 174 to 182 for all three different capital income shares. [Appendix B.1](#) presents the estimation results under the two settings of $3 \leq |\mathbf{C}_i| \leq 4$ and $4 \leq |\mathbf{C}_i| \leq 5$, and $\hat{\beta}$ varies from 0.53 to 0.58 for the first case, $\hat{\beta} \approx 0.4$ for the second case. Thus, even if each firm has 4 or 5 candidate cities, i.e., the fiscal competition is very fierce, the estimates of β don't ^{vary} ~~very~~ far from 0.46. And $\hat{\beta} = 0.46$ is a conservative estimate for the governments' revenue share since if we decrease the sizes of the choice sets, $\hat{\beta}$ will be higher than 0.5. [Appendix B.2](#) presents the estimation results under the different settings of action spaces of city governments, and it also shows $\hat{\beta} = 0.46$ is a conservative estimate.

To conclude, $\alpha = 0.5$ is a valid calibrated value, and $\hat{\beta} = 0.46$, $\hat{\sigma} = 177$ are robust estimates. We will use $\alpha = 0.5$, $\hat{\beta} = 0.46$, $\hat{\sigma} = 177$ in the remaining analysis of the paper.

6.2 Discussion of the estimation results

As Table 3 shows, the city governments' revenue share of firms' output is quite high ($\hat{\beta} \approx 0.46$), which is consistent with our assumption that attracting industrial firms to land in a city's jurisdiction will generate huge potential benefits for the city government by the fiscal externality or spill-over effects.

To clearly illustrate this point, we can do a thought experiment: We assume the only benefits city governments can get from landing new firms is the value-added tax (VAT) revenue and the city government officials think they can get the benefits in five years after the new firm landed.²²

We also assume the labor income is 70% of firms' output, which might be overestimated since $\alpha = 0.3$ in this case. Since we know the average profit ratio of industrial firms in 2012 is 6%,²³ thus, we can assume the taxable added value is 80% of the firms' output, which is also an overestimated figure.

We know the VAT rate is 17%, the share of city government in VAT revenue is 25%, and the back-of-envelop calculation shows that the city government's revenue share is $5 \times 80\% \times 17\% \times 25\% = 0.17$, which is 37% of $\hat{\beta} \approx 0.46$.²⁴ Thus, attracting new firms brings city governments a huge amount of benefits besides the official tax revenue, such as promoting local business, boosting the housing market, etc. The fiscal externality of attracting industrial firms is huge.

6.3 Fit of the model

To check whether our model characterizes the fiscal competition between city governments properly, We discuss the fit of the model in this section.

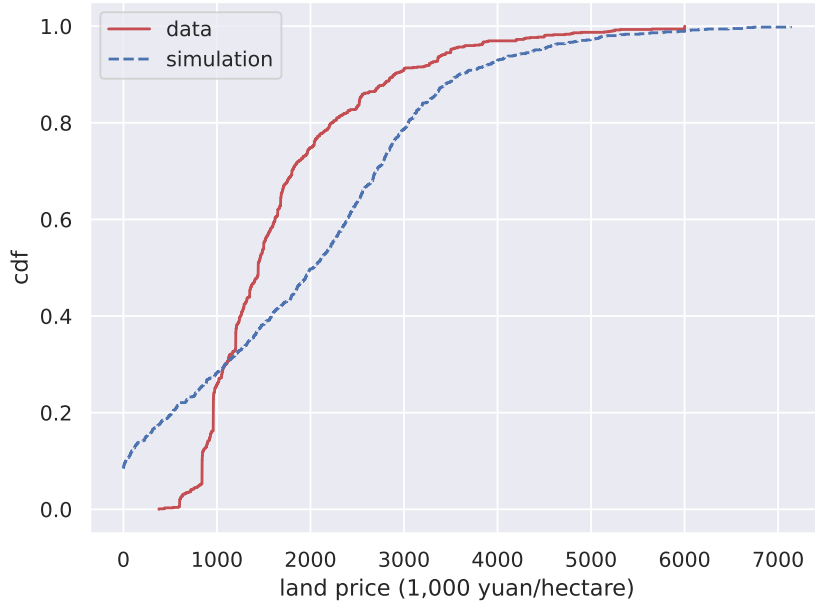

We compare the distributions of observed land prices and simulated land prices in Figure 4 and Table 4.

²²10 years is an overestimated term since the average term for Chinese city communist party secretary and mayor are 3.6 years and 3.2 years respectively during 2000-2010, see <https://www.yicai.com/news/3106338.html>.

²³This profit ratio (6%) is calculated by the National Bureau of Statistics of China, see http://www.stats.gov.cn/tjsj/zxfb/201301/t20130127_12932.html.

²⁴According to a survey conducted by Chinese Academy of Fiscal Sciences, the ratio of firm tax to added value is around 6.6% in 2013, see https://finance.ifeng.com/a/20170124/15166377_0.shtml, which is much lower than $80\% \times 17\% = 13.6\%$, thus, our comparison is very conservative.

Figure 4: Comparison of empirical CDFs of observed land prices and simulated land prices

Notes: We set $\beta = 0.46$, $\sigma = 177$ to do 30 simulations, and use the average of the expected land price in these simulations as the simulated land price.

Figure 4 shows the empirical CDFs of both observed land prices and simulated land prices. And the two empirical CDFs are close though there are more high prices in simulation.

Table 4: Descriptive Statistics of Observed Prices and Simulated Prices

	observed price	simulated price
mean	1685.097	1977.975
std	934.952	1395.534
min	379.505	0.000
25% percentile	978.617	818.128
median	1440.007	2030.870
75% percentile	2015.520	2853.654
max	6001.559	7134.401

Notes: $N = 1019$. We set $\beta = 0.46$, $\sigma = 177$ to do 30 simulations, and use the average of the expected land price in these simulations as the simulated land price.

Table 4 shows the descriptive statistics of the observed prices and simulated prices. The mean and 25% percentile of simulated prices are matched well to observed prices. But the standard error, median, and 75% percentile of simulated prices are not matched well to observed prices. This is because our model is parsimonious, and the model may not explain the second-order moment of land price very well. Another reason for the relatively poor matches of the median and 75% percentile of land prices is that we don't use the higher-order moments in the estimation, since higher-order moments are difficult to be precisely computed within a finite

number of observations (Adda and Cooper, 2003).

Think about phrasing
this in terms of
inefficiency of allocation
(?)

7 Counterfactual Analysis

In this section, we discuss the implications of the model by constructing three counterfactuals. First, we examine whether the fiscal competition characterized by the model can improve allocation efficiency by changing the locations of firms. Second, we analyze the potential impacts of suppressing the fiscal competition between city governments on industrial land prices and fiscal revenues. Third, we discuss the potential impacts of rising urban wages on the fiscal competition.

7.1 Allocation efficiency

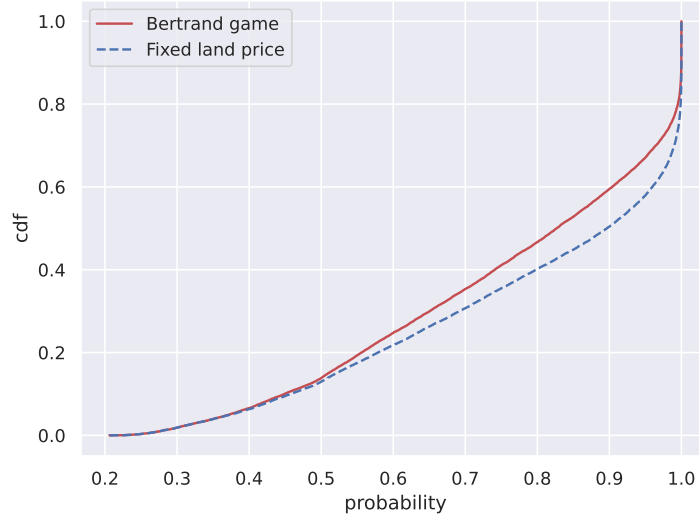

As we discussed in [Section 1](#) and [Section 2](#), the potential benefits of fiscal competition between cities is the improvement of resource allocation between cities. More specifically, cities that are disadvantaged in attracting firms (wage levels are high in these cities) can increase the probability of landing the firms by decreasing the land price more sharply than their competitors. But the extent of these benefits is unclear, since the sharp decreases of prices by disadvantaged cities may also promote other cities to decrease their prices, and probabilities of getting the firm across cities may not change by a lot.

To measure the exact impact of fiscal competition, we consider the counterfactual that the central government bans all these fiscal competitions by fixing the industrial land price across the whole country. If the land price is fixed, the city with the lowest wage level among the candidates of a firm will have the highest probability of landing the firm. And we denote these cities as advantaged cities.

We use the change of the probabilities of the advantaged cities landing the firms to measure the impact of fiscal competition on allocation efficiency. If fiscal competition decreases these probabilities significantly, the disadvantaged cities will have higher chances to get the firms, i.e., fiscal competition may be helpful to improve allocation efficiency.

We also do thirty simulations for both fiscal competition and fixed land price cases, and the empirical distribution of the probability of getting the firm in the fixed land price case is shown with the baseline case together in the [Figure 5](#) below.

Figure 5: The empirical CDF of the probability of getting the firm for advantaged cities

Notes: We set $\beta = 0.46$, $\sigma = 177$ to do thirty simulations, and calculate all the choice probabilities in the $N \times S$ (1019×30) location choice problems to draw the empirical distribution.

If we compare the empirical CDF of the highest probability of getting the firm in the Bertrand game with which in the case of nationwide fixed land price (see Figure 5), we will find that they are very similar, though the empirical CDF curve of the Bertrand game is slightly higher than which of the fixed land price case, i.e. the highest probability in the Bertrand game is stochastically dominated by that in the fixed land price case. This implies that the impact of fiscal competition on the locations of firms (allocation efficiency) is very small though fiscal competition indeed gives some disadvantaged cities higher chances of landing the firms.

We also show the descriptive statistics of the probability of getting the firms for advantaged cities in Table 5 below. It shows that fixing the land price (banning the fiscal competition) will increase this probability by only 2.8% on average and 7% for the median, which verifies again that the impact of fiscal competition on allocation efficiency is very small.

Table 5: Empirical distribution of probability of getting the firms for advantaged cities

	fixed land price	Bertrand game	difference
mean	0.802	0.774	0.028
std	0.218	0.215	0.003
min	0.206	0.206	0.000
25% percentile	0.636	0.602	0.034
median	0.897	0.827	0.070
75% percentile	0.996	0.984	0.012
max	1.000	1.000	0.000

7.2 Potential impacts of fiscal centralization

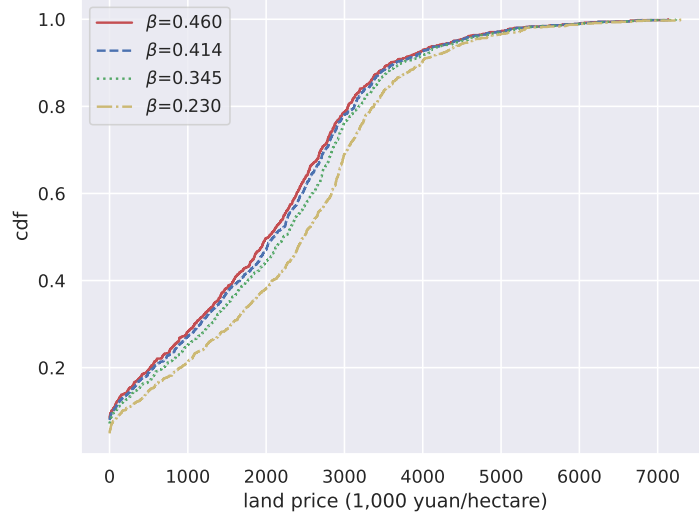

As we discussed in [Section 6.2](#), the estimates of $\hat{\beta} = 0.46$ is much greater than the official tax revenue share. Such large city governments' revenue share of firms' output reflects not only the strong incentive of local officials to attract firms, but also the significant economic and fiscal power of local officials, which can convert the spillover effects of industrial firms on local businesses, the housing market, etc., to their fiscal revenue. Moreover, as [Kroeber \(2020\)](#) observed: *"The ability of these leaders (local officials) to act independently of central dictates, and in response to local needs, has contributed to China's resilience and dynamism."* However, the fierce fiscal competition between local governments due to this ability may also waste a lot of potential fiscal revenue in the industrial land market as we discussed before.

The autonomy of local officials in economic affairs declines significantly after 2013 due to the re-centralization of the governance structure in China and the anti-corruption movement, and we call this change "fiscal centralization" reflected by the decrease of β .

We examine the potential impacts of the decrease of β by counterfactual experiments. Specifically, we decrease the estimated $\hat{\beta}$ by 10%, 25%, 50% respectively, and do thirty simulations to observe the change in the average land price, total land selling revenue and total fiscal revenue across all firms in our data set.

The change of land price distribution is shown in the following [Figure 6](#), which draws the land price distribution across all firms for the original estimates $\beta = 0.46$, $\beta = 0.414$ (10% decrease), $\beta = 0.345$ (25% decrease), and $\beta = 0.23$ (50% decrease). The figure shows that as β decreases, the empirical CDF curve of land price shifts to the right, which means more lands are sold at higher prices as β decreases. However, for $\beta = 0.414$ and $\beta = 0.345$, the empirical CDFs are close to the baseline ($\beta = 0.46$). Thus, the impact of fiscal centralization on land prices is limited.

Figure 6: Change of land price distribution due to decrease of β

Notes: The estimates $\hat{\beta} = 0.46$, $\beta = 0.414$, 0.345 , 0.230 are equivalent to 10%, 25%, 50% decrease of $\hat{\beta}$ respectively. For each β , we do 30 simulations for each firm to draw the empirical CDF plot.

The reason behind this change of price distribution is reflected by the trade-off between land-selling revenue and the fiscal revenue generated by landing the firm, which is characterized by equation (7). Intuitively, as the governments' revenue share of firms' output β decreases, the expected fiscal revenue of attracting firms using low land prices also decrease. Thus, the local officials care more about land-selling revenue even though higher land prices will decrease their probability of getting the firms. However, even if β decreases by 25%, the spillover effects of attracting firms are still sufficiently large, as we discussed in Section 6.2. Thus, the rise of land prices is limited.

We also calculate the percent changes in the average land price, total land selling revenue, and total fiscal revenue at different values of β , and the results are shown in the following Table 6. Notice that Table 6, the average land price and total land selling revenue increase as β decreases, but the increase is not large compared to the decrease of β . However, we also notice that the total fiscal revenue, which is the summation of total land selling revenue and total output share decreases sharply as β decreases. This is because the land-selling revenue constitutes only a small proportion of the total fiscal revenue compared to the huge revenue generated by landing firms.

Table 6: The impacts of decrease in β

β	change of β	average land price	total land selling revenue	total fiscal revenue
0.414	-10%	2.54%	1.96%	-9.02%
0.345	-25%	7.13%	5.58%	-22.49%
0.230	-50%	17.43%	13.97%	-44.75%

To conclude our discussion in this subsection, the trend of fiscal centralization after 2013 might restrict the fiscal competition between local governments and increase the industrial land price if the total output level across the nation is stable. However, the increase in land price is limited, and the loss of fiscal revenue due to the decrease in local governments' output share is difficult to be compensated by the increasing industrial land-selling revenue. Thus, fiscal centralization poses challenges for the central government in how to compensate the local governments' potential fiscal revenue loss.

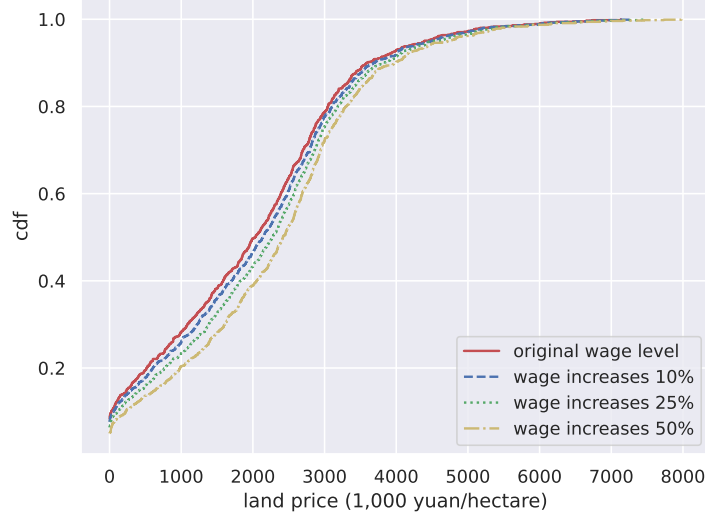

7.3 Potential impacts of the rising wage level

In recent years, the impacts of rising urban wages on China's economy are intensely discussed in both economic literature and public policy debates. The rising urban wage in China after the late 2000s is caused by the rural surplus labor crossing the Lewisian turning point (Cai and Wang, 2010) and the age structure change of population (Cai, 2016). We are particularly interested in the potential impacts of the rising urban wage on the fiscal competition between city governments characterized by our model since labor and land are both inputs in the firm's production function.

To implement the counterfactual analysis, we increase the wage level in all cities by 10%, 25%, and 50% respectively, and examine the impacts on average land price, total land selling revenue, total fiscal revenue by simulations.

We draw the empirical distributions of industrial land price under different rises of wage in the following Figure 7. As Figure 7 shows, the new empirical CDF curves of land price are close to the baseline if wage increases by 10% or 25% in all cities. If the wage level rises by 50% in all cities, the distribution shifts to the right more clearly. Nevertheless, all three cases show that the average land price is higher if the wage level increases in all cities.

Figure 7: Change of land price distribution due to increase of wage

Notes: $\beta = 0.46$, $\sigma = 177$ in all four cases. We do thirty simulations for each firm to draw the empirical CDF plots.

The intuition behind the rise of average land price as wage level increases in the whole nation is that labor and land are both inputs in the firm's production function, and the national-wide wage increase will make the relative price of labor to land more expensive than before. In other words, firms will be more sensitive to labor costs in their location choice problem than before, and city governments will rise the land price since firms are not as sensitive to land prices as before.

We also show the impacts of the increase of wage on average land price, total land selling revenue, and total fiscal revenue in the Table 7 below. We notice that the average land price increases as the wage level increases, but the increase is not sharp.

Table 7: The impacts of rising wage level

wage increase	average land price	total land selling revenue	total fiscal revenue
10.00%	4.00%	5.42%	0.44%
25.00%	9.31%	12.70%	1.04%
50.00%	16.68%	23.14%	1.90%

To conclude our discussion in this subsection, we think the rising urban wage will increase the average industrial land price in China slightly, i.e. restrict the fiscal competition, but just to a small extent. This implies it is difficult to change the pattern of fiscal competition by the change of production factor prices (pure market power).

8 Conclusion

In this paper, we have developed and estimated a static Bertrand game model between city governments in China as they use land sales discounts to attract industrial firms. The estimates show local governments can get huge benefits from attracting industrial firms. This implies that the ratio of fiscal revenue to firms' output is much higher than the official tax rate.

We show that if the total output level in China doesn't change a lot by fiscal competition, i.e., firms still want to produce in China if the land price is decided by market power, the major tool for fiscal competition: selling industrial land at low prices cannot improve the allocation efficiency of output but waste potential land-selling revenue. In this sense, our study not only sheds light on the mechanism of fiscal competition with Chinese characteristics, but also supports the tax competition model (Wilson, 1999) in the public economics literature. The counterfactual analysis also shows that the mode of fiscal competition faces potential challenges, such as the decline of economic autonomy of local governments and rising wages. This may also imply the potential change in the pattern of fiscal competition between Chinese local governments in the future.

However, our study doesn't imply the fiscal competition between city governments in China is worthless. The real potential benefits of fiscal competition can come from the case that more firms (or higher output levels) are created due to the lower production cost induced by the efforts of local governments to attract firms. But this issue is beyond the scope of our analysis since the firm's output level is exogenous in the model, and we don't consider the entry and exit problems of firms. Analyzing these issues can be a possible extension of the paper.

Incorporating a labor market into our model might be another interesting extension since local governments can use policy instrument (e.g. household registration system reform, enhancing social welfare, etc.) to attract workers to their jurisdictions and decrease the production cost of firms indirectly. And we leave these two possible extensions for further studies.

Appendix A: Proofs of the Theorems

Proof of Theorem 1. $f(p_{min}) \leq 0$ implies $\frac{\partial v_{ik}}{\partial p_{ik}} < 0$ for all $p_{ik} \in [p_{min}, p_{max}]$, thus city government k will sell the land at the minimum price. The same logic holds for the case where $f(p_{max}) > 0$. If $f(p_{min}) > 0$ and $f(p_{max}) < 0$ ($f(p_{min}) < 0$ and $f(p_{max}) > 0$ is impossible since $f(p_{ik})$ is decreasing on \mathcal{R}), there must be exact one p_{ik} on $[p_{min}, p_{max}]$ s.t. $\frac{\partial v_{ik}}{\partial p_{ik}} = 0$, which is exactly the F.O.C. of k 's expected fiscal revenue maximization problem. \square

Important for the main argument \rightarrow should not be in (-)

Proof of Theorem 2. For any Bertrand Game $\langle \mathbf{C}_i, (S_{ik}), (v_{ik}) \rangle$, we set $N = |\mathbf{C}_i|$ and drop the subscript i for convenience. And we define another mapping $F: \mathbb{R}^N \rightarrow \mathbb{R}^N$, s.t. $F(p) = p'$: for $k = 1$, p'_k is the root of $f(p_k) = 0$ given $p_{(-k)} = (p_j)_{j \neq k}$. As defined in Section 3.4:

$$f(p_k) = 1 - \frac{1}{\sigma m} (1 - P_k(p_k, p_{(-k)})) (\beta Y + p_k T)$$

this does not fully describe the mapping, does it? More clear definition would help

We fix k and denote the choice probability for city j by $P_j \equiv P_j(p'_k, p_{(-k)})$ for $\forall j$, i.e., the price vector is fixed as $(p'_k, p_{(-k)})$. We define a metric ρ on S^N : $\rho(p, q) = \max_k |p_k - q_k|$.

It can be shown that the p'_k is a continuous function of $p_{(-k)}$. We differentiate both sides of $f(p'_k) = 0$ w.r.t. p_j ($j \neq k$) and rearrange it, then we get:

$$\frac{\partial p'_k}{\partial p_j} = \frac{\frac{1}{m\sigma} P_k P_j (\beta Y + p'_k T)}{\frac{1}{m\sigma} P_k (1 - P_k) (\beta Y + p'_k T) + (1 - P_k)} < \frac{P_j}{1 - P_k}$$

Refer to theorem 1

(which should probably state it as well?)

Then from the mean value theorem, we know for any $p, q \in S^N$:

Need continuity of $F(p)$

$$|F(p)_k - F(q)_k| = |\nabla p'_k(\hat{p}_{(-k)}) \cdot (p_{(-k)} - q_{(-k)})|$$

$$< \sum_{j \neq k} \frac{\hat{P}_j}{1 - \hat{P}_k} \rho(p, q)$$

(16)

$$\stackrel{?}{\Rightarrow} \rho(p, q)$$

Seems that a direct proof using definition of contraction mapping would be easier

where $\nabla p'_k$ is the gradient of p'_k evaluated at some $\hat{p}_{(-k)}$ between $p_{(-k)}$ and $q_{(-k)}$, $\hat{P}_j = P_j(p'_k, \hat{p}_{(-k)})$.

From Eq. (16) and the definition of G we have:

where?

$$|G(p)_1 - G(q)_1| \leq |F(p)_1 - F(q)_1| < \rho(p, q)$$

Then we redefine $p^* = [G(p)_1, p_2, \dots, p_N]$, $q^* = [G(q)_1, q_2, \dots, q_N]$, using (16) again, we have

where from?

$$|G(p)_2 - G(q)_2| \leq |F(p^*)_2 - F(q^*)_2| < \rho(p^*, q^*) \leq \rho(p, q)$$

Iteratively, we can prove $|G(p)_k - G(q)_k| < \rho(p, q)$ for $\forall k$, i.e., $\rho(G(p), G(q)) < \rho(p, q)$.

We have proved that G is contracting on the compact set $S^N = [p_{\min}, p_{\max}]^N$. Thus, G has a unique fixed point p^* , and $G^n(p) \rightarrow p^*$ for any $p \in S^N$ as $n \rightarrow \infty$. Since p^* is a pure NE if and only if p^* is a fixed point of G , the Bertrand game has a unique pure NE. \square

This seems correct!

Appendix B.1: Estimation Under Different Settings of Choice Sets

We present the estimation results under the other two settings of the choice sets \mathbf{C}_i here.

First, instead of equation Eq. (12), we set $|\mathbf{C}_i| = 3$ if $Y_i \leq \text{Median}(Y)$, $|\mathbf{C}_i| = 4$ if $Y_i > \text{Median}(Y)$. The estimation results are shown in Table 8 below.

Table 8: Estimates of Parameters ($3 \leq |\mathbf{C}_i| \leq 4$)

Calibrated α	Parameters	Estimates	Standard Error
0.33	β	0.532	0.044
	σ	183.951	22.993
0.5	β	0.575	0.047
	σ	193.045	24.373
0.67	β	0.580	0.048
	σ	196.082	25.872

As Table 8 shows, the estimates $\hat{\beta} \approx 0.53, 0.58, 0.58$ for $\alpha = 0.33, 0.5, 0.67$ respectively. Thus, $\hat{\beta}$ under this setting are higher than our main results due to the decrease of the size of choice sets since the fiscal competition is less fierce than the settings in the main text if we fix β , and $\hat{\beta} = 0.46$ is a conservative estimate.

Second, we set $|\mathbf{C}_i| = 4$ if $Y_i \leq \text{Median}(Y)$, $|\mathbf{C}_i| = 5$ if $Y_i > \text{Median}(Y)$. The estimation results are shown in Table 9 below.

Table 9: Estimates of Parameters ($4 \leq |\mathbf{C}_i| \leq 5$)

Calibrated α	Parameters	Estimates	Standard Error
0.33	β	0.393	0.026
	σ	178.190	22.718
0.5	β	0.379	0.027
	σ	197.563	25.374
0.67	β	0.387	0.028
	σ	203.422	26.100

As Table 9 shows, the estimates $\hat{\beta} \approx 0.4$ in both cases of $\alpha = 0.33, 0.5, 0.67$, which is slightly lower than the main results in Table 3. However, the setting that half of the firms have 4 candidate cities and the other half have 5 candidate cities makes the competition for firms very fierce even for a smaller β , thus, the estimates in Table 9 indeed verifies the robustness of our main results in Table 3 since $\hat{\beta}$ is not far away from 0.46 even if the fiscal competition is extremely fierce.

Appendix B.2: Estimation Under Different Participation Constraints

We present the estimation results under the other two settings of participation constraints (action space) here. The specification of choice set \mathbf{C}_i here is the same as which in the main text ($3 \leq |\mathbf{C}_i| \leq 5$).

First, we try to shrink the action space and set $p_{min}^i = \max\{0, p_{obs}^i - 1000\}$, $p_{max}^i = p_{obs}^i + 1000$. The estimation results are shown in Table 10 below.

Table 10: Estimates of Parameters ($3 \leq |\mathbf{C}_i| \leq 5$, smaller action space)

Calibrated α	Parameters	Estimates	Standard Error
0.33	β	0.544	0.055
	σ	172.411	29.692
0.5	β	1.350	1.056
	σ	104.241	34.809
0.67	β	0.545	0.056
	σ	175.176	29.811

As Table 10 shows, the estimates of β are higher than $\hat{\beta} = 0.46$ in the main text. But the standard error of $\hat{\beta}$ for $\alpha = 0.5$ is extremely large, which implies there might be a weak identification problem when the action space is small. Thus, the specification of action space is less appropriate than which in the main text.

Second, we try to expand the action space and set $p_{min}^i = \max\{0, p_{obs}^i - 3000\}$, $p_{max}^i = p_{obs}^i + 3000$. The estimation results are shown in Table 11 below.

Table 11: Estimates of Parameters ($3 \leq |\mathbf{C}_i| \leq 5$, larger action space)

Calibrated α	Parameters	Estimates	Standard Error
0.33	β	0.909	0.331
	σ	159.155	36.127
0.5	β	0.561	0.038
	σ	221.592	29.310
0.67	β	0.583	0.038
	σ	226.435	27.515

As Table 11 shows, the estimates of β are higher than $\hat{\beta} = 0.46$ in the main text. However, the standard error of $\hat{\beta}$ for $\alpha = 0.33$ is very large, which implies there might also be a weak identification problem when the action space is too large.

Notice that in both Table 10 and Table 11, the estimates of β with small standard errors

vary from 0.54 to 0.58, thus, we can still think $\hat{\beta} = 0.46$ is a conservative estimate. To conclude, the specification of action space in the main text is appropriate for our analysis.
